Signature Verification Using Few Shot Learning

Shruti Gadilkar, Smital Jamadar, Vedant Akhade, and Dr.Anamika Jain

Dept of Computer Engineering, Ajeenkya D.Y. Patil School of Engineering , Lohegaon, Pune.

Abstract-Offline signature verification is a very common biometric authentication method in fields like banking, legal docs, and access control. But we see that it's an issue of the fact we have few genuine signature examples per each user. In such few shot settings traditional Convolutional Neural Network based classification models tend to overfit what little training data they do have and also see an increase in false accept rate which in turn makes them unreliable for security sensitive applications.

To present a solution to this issue our work puts forth a metric learning based verification framework which uses a Siamese Network in conjunction with a prototype based decision strategy. We have designed the Siamese Network to learn discriminative feature representations which it does via contrastive loss thus improving the separation between what is real and what is fake in signatures. Also we see that the prototype based verification stage which puts into play comparison of a query signature with that of a set of representative genuine reference embedding's improves the overall stability of the verification process.

The presented framework is put to test in a very challenging 5 shot cross-dataset setting which we used the GPDS, MCYT, and CEDAR offline signature datasets for. We report that we see great generalization performance, which achieved max accuracy of 94.16% on GPDS, 93.44% on MCYT, and 93.07% on CEDAR. These results we put forth as proof of the method's robustness and practical value for use in real world signature verification which by nature of the fields is data sparse and cross domain

1. INTRODUCTION

Offline handwritten signature verification is a very popular form of behavioral biometric authentication which is extensive in use within banking, legal and financial fields due to its social acceptability and non-intrusive nature [1], [19]. Although very wide scale, what we get out of it is still in its early stages in terms of performance which we put down to high intra-class variation in which we see great diversity in genuine signatures from different times and conditions like mood and writing speed, also we see not enough difference between the real and the forgeries which causes issues [1], [22]. Figure.01 we see examples of genuine and forged signatures.

In different attack settings, very well done forgeries pose the greatest challenge in offline signature verification systems. In such a situation which is the scenario that a person -- that which is not the real owner studies in detail, and reproduces the real author's style, the real look and structure of the signed content. Also as a result these high quality forgeries put out which very much looks like the real thing to the eye that they present great issue in their detection by auto systems, in, [7], and [8].

Recent reports show that which in the field of metric learning including a great success of Siamese Neural Networks (SNNs) in few shot signature verification. These networks

we see to be which at the task of creating discriminative feature embedding' by which they reduce the distance between genuine signatures and at the same time put forgeries as far apart as possible [9], [22]. Also which has come to the fore is the use of prototypical learning in few shot classification which uses a prototype for each class that is the mean of support sample embedding's which in turn enables what we see to be very robust generalization in cases of data sparsity [6], [11], [13].

In this study we present a combined Siamese Neural Network and Prototypical Learning approach for offline handwritten signature verification which we did so within a very strict 5 shot enrollment protocol. The Siamese network we used is trained via contrastive loss to develop writer discriminatory embedding and at the same time we built per user prototypes out of true enrollment embedding averages. For the verification we used cosine similarity and also implemented a threshold based decision which in turn we did for the purpose of improving interpretability and at the same time we improved robustness against skilled forgeries.

GPDS-300, MCYT-100, and CEDAR. Of these GPDS-300 is used as the primary evaluation benchmark because of it's large scale and the fact that we have at hand skilled forgeries which in turn makes it a good fit for real world security assessment [1], [10]. We report that the put forth approach does indeed achieve performance that is very much in the same range as other methods and also we see that we do very well in terms of resistance to skilled forgeries which we note is even under difficult few shot learning conditions.

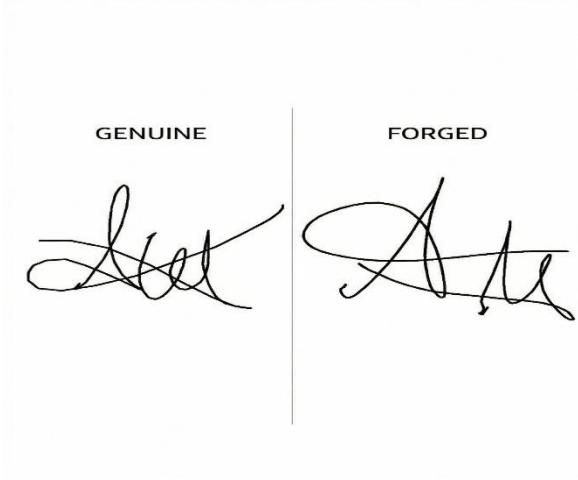

Figure 1: Examples of genuine and forged signature samples.

2) LITRATURE REVIEW

Offline handwritten signature verification remains one of the most accepted biometric techniques in banking, legal documentation, and access-control systems because signing is already part of many real-world processes. At the same time, it is still a difficult pattern-recognition problem. Genuine signatures which are from the same person may vary because of speed, pressure, or writing conditions, while forgeries do preserve many visual traits of the original signature. The problem becomes even harder during enrolment, in which only few numbers of genuine samples are usually available for each user. This practical limitation has pushed the recent researches toward scientific data-efficient learning strategies for signature verification [1], [4].

Earlier work in field of offline signature verification highly would be depended on handcrafted descriptors and conventional classifiers models. Hafemann et al. [1] reviewed several decades of research and showed how global, local, and texture-based features were commonly combined with models such as support vector machines. These methods established a useful baseline,

but their performance highly depended heavily on the manual feature design. This drawback became more evident in cases with high intra-class variation and limited training samples, in which handcrafted pipelines were mainly less flexible [1].

Multiple studies attempted to improvise this classical approach with stronger feature representations. Kumar [2] combined an ensemble of the self-crafted features with an SVM to improvise the robustness against forgeries, while Zhou et al. [3] also proposed combined multiple features which captured both structural and statistical data from signatures. Related work by Jain et al. [28] used geometrical features together with an artificial neural network classifier to improve discrimination, and Jain et al. [29] extended this task through a multi-label framework which could verify signatures and also identifying forgery. These studies showed that engineered features can still be useful, but they did not fully solve the problem of learning reliably from only a few genuine samples per writer [2], [3], [28], and [29].

A huge shift in the domain came with the use of deep learning, especially with convolutional neural network, which gradually reduced the need for manual feature extraction technique by learning representations straight from the signature images. Rokade et al. [5] proved that CNN-based models can outperform old traditional handcrafted approaches by learning more patterns of discriminative features. Similar improvements were discussed by Abdirahma et al. [19], and Jain et al. [27] showed that even shallow CNN architectures can perform effective verification with lower computational cost. Even so, most deep models still depend on larger labelled datasets, which limits their usefulness in realistic enrolment settings with very few genuine samples per user [5], [19], and [27].

These limitations has increased the interest in few-shot learning and meta-learning, where the end-goal is to generalize from a very few supports set images. In the broader machine-learning literature, Triantafillou et al. [8] studied few-shot learning from a data-retrieval motive, while Li et al. [9] reviewed deep metric-learning methods for similarity-based classification. Gharoun et al. [7] also surveyed meta-learning techniques that support rapid adaptation to new tasks with minimal data. These ideas are especially relevant to signature verification because real enrolment conditions naturally resemble a few-shot setting [7], [8], [9].

Within signature verification itself, multiple studies have been directly focused on the low-support set problem. Chang and Wu [4] developed a verification model for small-sample conditions. Hafemann et al. [11] explored meta-learning for fast adptation to new users, and Tsourounis et al. [12] furthermore demonstrated the value of few-shot learning for offline handwritten signatures in a very scarce-data environments. Together, these works show that data-efficient learning is not simply a technical preference, but a practical requirement for deployable verification systems [4], [11], [12].

Among the models proposed for such settings, Siamese architectures have become especially important because signature verification is naturally a similarity-comparison task. Instead of learning rigid class boundaries, Siamese networks learn an embedding space in which genuine pairs are close and forged pairs are far apart. Das et al. [22] showed that Siamese neural networks improve writer-independent verification, and Sekhar et al. [20] proposed OSVNet to improve robustness against intra-class variation and skilled forgeries. Iamleelaporn et al. [13] introduced a Double Siamese

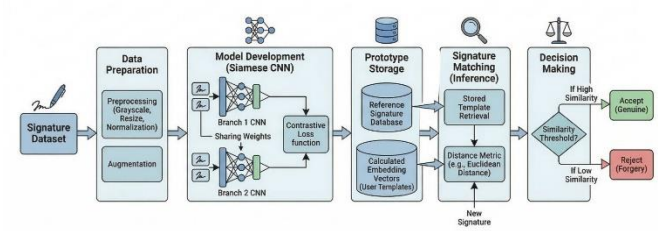
Network for a very stronger discriminative learning method, while Majumder et al. [14] combined Siamese modelling with transformer-based attention to better capture long-range structural dependencies in signatures [13], [14], [20], [22].

Researchers have also explored complementary approaches. Djoudjai et al. [6] investigated symbolic data analysis within a few-shot framework so to better handle and understand variability under lower data conditions. Xiao and Wu [15] applied spatial transformer networks to reduce the effect of geometric distortion and misalignment, while De Moura et al. [21] proposed a stream-based approach that supports continuous enrolment and adaptation in practical systems [6], [15], [21].

Progress in this domain has also been highly dependent on fair evaluation and analysis. Tolosana et al. [10] highlighted the main importance of standard protocols through the SVC-ongoing competition, while the application-oriented studies taken place such as Sharma [16] in banking and Han et al. [17] in multimodal verification show that few-shot ideas are becoming increasingly relevant beyond academic benchmarks. Overall, the literature visibly shows a transition from handcrafted feature engineering model to advanced deep learning, and then to few-shot, metric-learning, and various adaptation-based methods. However, robust detection of skilled forgeries, stable cross-dataset performance, and reliable verification with very limited enrolment data remain open challenges, which motivates the development of more adaptive and data-efficient models for offline handwritten signature verification [10], [16], [17].

3. Proposed Methodology

The proposed methodology system deeply focuses to perform offline handwritten signature verification under a very strict few-shot conditions, it means only a limited number of genuine signature samples are available per user. To work effectively under that constraint, a metric-based deep learning method is adapted to make learning a better similarity patterns and improve generalization in the model.



3.1 Preprocessing

To ensure consistent data across datasets and improve the model stability, persistency and functionality the following preprocessing steps were applied:

3.1.1 Grayscale Conversion

All given signature images were converted to grayscale format to eliminate the colour information and focus completely on structural stroke patterns.

3.1.2 Image Resizing

Each image was then resized to a fixed resolution of: 160 × 120 pixels

This make sure that we have uniform input dimensions for the convolutional neural network and reduces any computational complexity.

3.1.3 Intensity Normalization

The Pixel intensity values were normalized to the fixed range: [0, 1]

This was achieved by dividing pixel values by 255. Normalization does stabilizes the training and also prevents gradient imbalances.

3.1.4 Embedding Extraction and L2 Feature Normalization

After preprocessing step, each refined signature image is passed through the Siamese convolutional neural network to obtain a 128-dimensional embedding vector:

$z = f_\theta(x) \in R^{128}$..... (1)

Where f_θ denotes the learned embedding function.

Where x represents the Input Signature image.

Where R denotes the set of real values.

Where z denotes Output feature vector

(Embedding's).

To ensure the scale invariance and stabilize similarity computation, L2 normalization is applied straight after the embedding extraction, resulting in:

$\hat{z} = \frac{z}{\|z\|_2}$..... (2)

Where:

$\hat{z}$ denotes normalized embeddings.

$\|z\|_2 = \sqrt{\sum_{k=1}^{128} z_k^2}$.....

This step guarantees that all embedding vectors lie on a unit hypersphere :

$\|\hat{z}\|_2 = 1$..... (3)

L2 normalization improves cosine similarity reliability and enhances threshold stability during verification, particularly in few-shot learning scenarios.

3.2.1 Problem Formulation

Offline signature verification is formulated as ab biometric verification task under limited data conditions.

Given a signature image

$x \in R^{H \times W}$,the objective is to learn an embedding function:

$f_\theta : x \rightarrow R^d$

Where:

H represent image height, **W** represents image width.

f_θ Is a deep neural network parameterized byθ, d is the embedding dimension, the learned embedding space ensures: Genuine signature of the similar user are close, Forged or impostor signature are far apart. The verification decision is based on a distance metric:

In this work, a strict 5-shot protocol is adopted, where only five genuine samples per user are available during enrollment.

3.2.2 Siamese Network Architecture

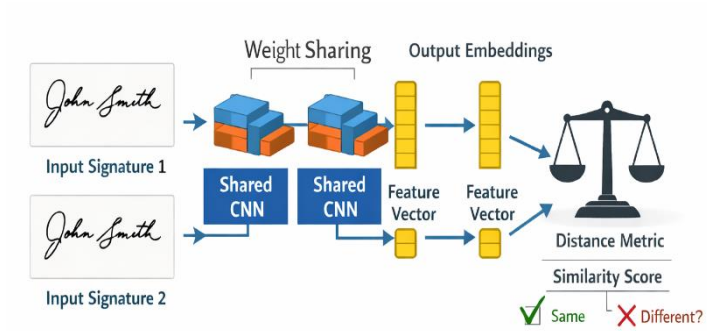


Figure 2 Siamese Network Architecture

To learn discriminative embedding's under few-shot constraints, a Siamese Neural Network (SNN) architecture is employed.

The Siamese network consists of two identical convolutional branches sharing weights. For a given pair of input signatures (X_1, X_2) the network computes:

$z_1 = f_0(X_1)$, $z_2 = f_0(X_2)$……. (4)

Where**:**

$z_1, z_2 \in R^{128}$ **……..... (5)**

Where Eq(5) are 128-dimensional embedding vectors.

3.2.3 Feature Extraction Backbone

Each branch includes:

- Convolutional layers
- Batch normalization
- ReLU activation
- Max-pooling operations
- Fully connected projection layers

The final fully connected layer outputs a compact **128** -dimensional embedding representing the structural characteristics of the signature.

The **shared-weight** architecture ensures consistent feature extraction across input pairs.

3.2.4 Contrastive Loss for Metric Learning

The Siamese network is trained using the Contrastive Loss function to enforce separation between genuine and forged pairs.

Let y € 0, 1 denote the label:

y=1for genuine pair,

y=0 for forged/impostor pair.

The Euclidean distance between embedding's is**:**

$D = \|z_1 - z_2\|_2$

The contrastive loss is defined as:

$L = y \cdot D^2 + (1 - y) \cdot max(0, m - D)^2$

Where L represents contrastive loss.

Where m is a margin parameter.

This loss encourages: Genuine pairs to have small distance, Forged pairs to be separated by at least margin m.

3.2.5 Prototypical Few-Shot Learning

To handle limited enrollment samples, a prototypical learning strategy is integrated.

For a user u, given K=5 genuine samples:

$\{x_1^u, x_2^u, x_3^u, x_4^u, x_5^u\}$

Their embedding's are computed as:

$z_i^u = f_\theta(x_i^u)$

The user prototype is defined as:

$p_u = \frac{1}{\kappa} \Sigma_{i=1}^{K} z_i^u$

Where p_u represents prototype of user u.

To stabilize similarity computation, L2 normalization is applied:

$\hat{z} = \frac{Z}{\|Z\|}$

$\hat{p}_u = \frac{P_u}{\|P_u\|_2}$

The prototype serves as a representative embedding of the enrolled user in the feature space.

3.2.6 Cosine Similarity-Based Verification

During authentication, a test signature $_T$ is embedded as:

The similarity between the test embedding and the stored prototype is computed using cosine similarity:

The cosine distance is then:

A decision threshold $_T$ is applied:

The optimal threshold is determined through threshold sweeping on evaluation data.

3.2.7 Overall System Architecture

The proposed framework consists of two primary phases:

1. Enrollment Phase

Collect 5 genuine signatures per user.

$x_1, x_2, x_3 x_4, x_5$

Preprocess each image (grayscale, resize, normalization).

Extract embedding's using Siamese CNN.

Compute user prototype by averaging embedding's.

After embedding + normalization:

$\hat{z}_1, \hat{z}_2, \hat{z}_3, \hat{z}_4, \hat{z}_5$

Store prototype in the database.

2. Verification Phase

- Input test signature.
- Apply preprocessing.
- Extract embedding via Siamese network.
- Compute cosine distance with stored prototype.
- Apply threshold decision.
- Output accept/reject decision.
- Architectural Flow

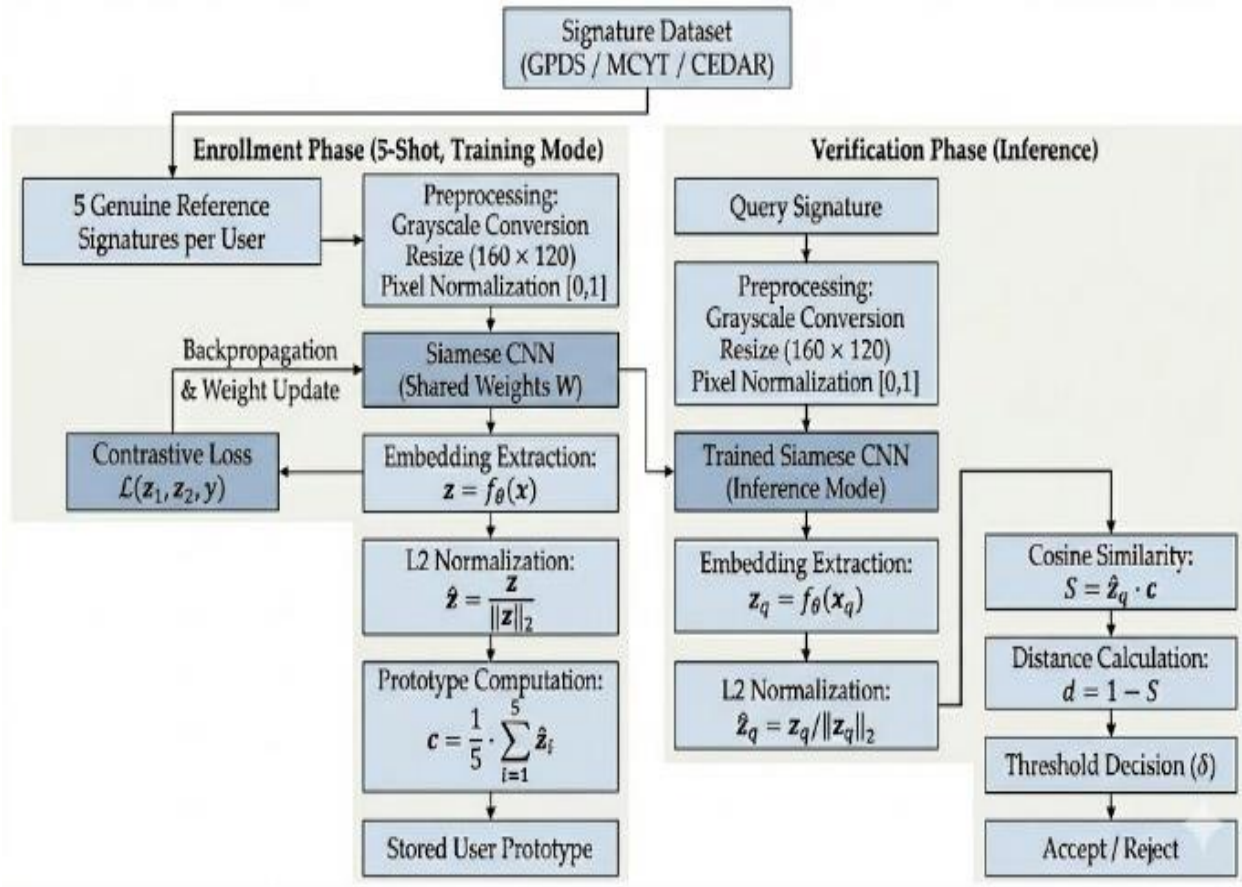

Figure 3 SYSTEM ARCHITECTURE

This architecture model enables a much scalable and writer independent verification under the limited training samples data conditions.

3.2.8 Training Strategy and Experimental Setup

To make sure robustness is achieved under few-shot conditions, the Siamese network is trained using a precisely designed metric-learning setup which incorporates the contrastive loss, early stopping, adaptive optimization, and threshold based biometric evaluation system.

3.2.8.1 Few-Shot Protocol

The system strictly follows a 5-shot sample protocol:

Only 5 genuine signatures per user are used here for the verification during enrolment. Remaining genuine samples are then used for testing purpose. All the forged samples are used for pretender evaluation.

This setup simulates a real-world biometric verification System registration where a limited amount sample are Available.

3.2.8.2 Loss Function

The Siamese network is trained using Contrastive Loss function, which directly optimizes the embedding space.

For a pair of signatures (x_1, x_2) with label

y € 0, 1:

$D = \|z_1 - z_2\|_2$

The contrastive loss is defined as:

$$L = y \cdot D^2 + (1 - y) \cdot max(0, m - D)^2$$

Where:

y=1 for genuine pairs

y=0 for forged pairs

m is the margin

This loss therefore minimizes the distance between genuine signatures and then applies partition between forged signatures.

3.2.8.3 Optimizer

The network parameters were optimized using the Adam optimizer, the Adam optimizer, also known as Adaptive Moment Estimation, is a stochastic gradient descent method which updates network parameters by evaluating mean and variance of the gradients to adjust learning rates.

Adam was selected due to its quick convergence and stability in a limited data sample scenerios. With:

Learning rate = 0.0005

The Siamese network was then trained using the given Adam optimizer with a learning rate of 0.0005

This learning rate was chosen empirical observations and by analyzing the given model's behavior and verification performance under the given 5-shot learning protocol.

In few-shot system case, where only a few number of genuine samples are available for per user, selecting a suitable learning rate is very important.

A slightly higher learning rate helps the network learn faster meaningful distinctions between genuine and forged signatures, mainly during the initial stages of training.

Through the experimental evaluation, it was evaluated that a learning rate of 0.0005enabled a stable system convergence while embracing the severability of the learned embedding's, without having any training instability.

Therefore, this learning rate value was selected as aproportionate choice which would support efficient optimization and relevant verification performance.

Batch size = 16

3.2.8.4 Early Stopping

To prevent over fitting under few-shot conditions:

- Training was monitored using average epoch loss.
- A patience value of 5 epochs was used.
- If loss did not improve for 5 consecutive epochs, training was stopped.
- The best-performing model was saved automatically.
- This significantly improved generalization across datasets.

3.2.8.5 Embedding Normalization

Before similarity computation, embedding's were L2 normalized:

Given query signature: x_q

Embedding: $z_q = f_\theta(x_q)$

L2 Normalization:

$\hat{z}_q = \frac{z_q}{\|z_q\|_2}$.

This stabilization improved cosine distance reliability and reduced FAR.

3.2.8.6 Threshold Optimization

Instead of using a fixed decision boundary:

- 100 threshold values were swept between minimum and maximum distances.
- The threshold maximizing accuracy was selected.
- FAR and FRR were computed at this optimal threshold.

This ensures dataset-specific calibration and fair biometric evaluation.

3.2.8.7 Implementation Details

Framework: PyTorch

- Image resolution: 160 × 120
- Embedding dimension: 128
- Training epochs: up to 50 (with early stopping)
- Execution: CPU-based training

4. Experimental Setup

In our experiments we used a modern computing platform which included a multicore processor and enough memory to support in depth learning tasks. We developed in Python, which in turn used PyTorch as the main deep learning system for its adaptability and in the support of metric learning models. Also, we then used other libraries for image processing, numerical computation, and performance review.

In a few shots learning the setting we used five sample of a person's true signatures for training each model. We used the Adam optimizer which had a fixed learning rate for training the Siamese Network and also, we did not train for too many epochs to avoid over fitting.

Model performance was analysed with respect to standard biometric verification measures which include Accuracy, False Acceptance Rate (FAR) and False Rejection Rate (FRR). The metrics evaluation report on the overall accuracy and security of the system.

4.1 Datasets

To evaluate the efficiency and generalization capability of the proposed few-shot signature verification framework, experiments were then conducted on three frequently used datasets: GPDS-300, MCYT-100, and CEDAR. Among these, GPDS-300 is considered the primary dataset for the performance comparison with existing literature due to its large scale and higher class variability.

4.1.1 GPDS-300

The GPDS − 300 dataset is one among the largest publicly available offline signature verification datasets. It contains signature samples from 300 different users, mainly including both genuine and forged signatures.

Each user contributes multiple genuine signatures and corresponding skilled forgeries, making the dataset highly suitable

for evaluating biometric verification systems under realistic conditions.

Due to:

- Its large number of users,
- Significant intra-class variability,
- Availability of skilled forgeries,

GPDS-300 is selected as the primary dataset in this study. Performance on GPDS is used as the principal benchmark for comparison with existing state-of-the-art approaches reported in the literature.

4.1.2 MCYT-100

The $MCYT - 100^2$ set includes the work of 100 writers which we have collected in both their natural and trained to look fake signature styles within a controlled setting.

Compared to GPDS, MCYT contains: In terms of GPDS, MCYT has:

•Cleaner acquisition settings,

•Moderate inter-class separation,

Skilled forgeries that reproduce the look of real writing.

MCYT is used for the evaluation of the put forth models performance in terms of robustness and cross dataset generalization in a medium scale biometric setting.

4.1.3 CEDAR

The $CEDAR^3$ collection of signatures has 55 writers' samples which include both genuine and forged samples [].

Although of a smaller scale CEDAR is still a very cited benchmark in the field of offline signature verification, it puts forth a balanced evaluation which also includes comparison to both traditional and deep learning based approaches.

- CEDAR dataset available in:

https://www.kaggle.com/datasets/shreelakshmigp/cedardataset

- MCYT-100 dataset available in :

https://bidalab.eps.uam.es/listdatabases?id=MCYT_Signature_100 (Access Available through this site)

- GPDS-300 dataset available in:

https://www.researchgate.net/figure/Sample-of-Signatures-GPDS-300-Dataset_fig2_383107539

4.2 Few-Shot Experimental Protocol

To in which we replicated real world biometric enrollment settings we implemented a 5 shot protocol across all data sets. For each user:

For the enrollment phase 5 genuine signatures were used.

Genuine signatures which were left out were used for testing.

All that which is forged was for testing.

In this study we present a real world scenario in which we have a few genuine samples per user at the time of system enrollment.

Evaluation Criteria :

To access the performance of the proposed signature verification system, three standard biometric evaluation metrics are used: **Accuracy, False Acceptance Rate (FAR), and False Rejection Rate (FRR).**

Accuracy represents the overall effectiveness of the system in correctly classifying both genuine and forged signatures. It indicates the proportion of total predictions that are correctly identified by the model.

False Acceptance Rate (FAR) measures the likelihood of the system incorrectly accepting a forged signature as genuine. This metric reflects the security of the system, as a higher FAR implies a greater risk of unauthorized access.

False Rejection Rate (FRR) represents the rate at which genuine signature images are incorrectly rejected by the proposed system after evaluation process. This metric is allied to user's convenience, as a higher FRR leads to inconvenience for genuine users.

An ideal efficient signature verification system always aims to achieve a higher accuracy while sustaining both FAR and FRR rate at nominal levels, securing a balance between security and usability**.**

5. Results and Discussion

5.1 Performance on GPDS (Primary Dataset)

GPDS was selected as the primary benchmark dataset for evaluating the proposed few-shot signature verification framework.

Under a strict 5-shot protocol, the Siamese network achieved:

After integrating per-user prototypical learning, the performance improved significantly:

This clearly demonstrates that prototype-based embedding aggregation improves decision stability and reduces false acceptance.

The reduction in FAR from **7.74%** to **2.42%** is particularly important in biometric systems, as lowering FAR directly increases system security against forgery attacks.

5.2 Performance on CEDAR Dataset

For the CEDAR dataset, we observed that improvement in performance with prototype-based evaluation compared to the standard Siamese Network evaluation. The results show that prototype aggregation improved the overall accuracy and provided a much stable representation of genuine signatures images. This states that the CEDAR dataset has responded positively to prototype-based matching and did not degrade the results. It also represented that the effect of prototype aggregation is dependent on few dataset-specific characteristics such as intra-class variation and forgery distribution. Overall, these results highlight that dataset tuning plays an important role of the performance of few-shot verification system.

5.3 Performance on MCYT Dataset

On MCYT, the Siamese network achieved: On MCYT the Siamese network performed:

Prototype based learning increased total accuracy which also saw balanced FAR and FRR.

MCYT reports that the put forth embedding based method does well.

Table.01 Dataset Accuracy Comparison

Evaluat-ion Method	**Dataset**	**Accuracy (%)**	**FAR (%)**	**FRR (%)**
Siamese Network Evaluation	CEDAR	87.91	11.39	12.83
Prototype-based Evaluation	CEDAR	93.07	4.24	10.33
Siamese Network Evaluation	MCYT-100	89.94	7.60	5.75

Evaluat-ion Method	Dataset	Accuracy (%)	FAR (%)	FRR (%)
Prototype-based Evaluation	MCYT-100	93.44	7.20	5.25
Siamese Network Evaluation	GPDS-300	89.13	7.74	14.00
Prototype-based Evaluation	GPDS-300	94.16	2.42	10.18

5.4 Dataset Accuracy Comparison

Prototype-Based Evaluation Accuracy

Table.02 Prototype-based Evaluation:

Sr.no	Dataset	Accuracy
01	GPDS	94.16
02	CEDAR	93.07
03	MCYT	93.44

Table.03Siamese Network Evaluation:

Sr.no	Dataset	Accuracy
01	GPDS	89.13
02	CEDAR	87.91
03	MCYT	89.94

Observations:

GPDS shows the strongest performance.

MCYT demonstrates consistent generalization.

CEDAR has greater difficulty in particular for prototype based evaluation.

Prototype learning performs well in GPDS and MCYT but is dependent on the dataset.

Interpretation:

Our method performs at the level of state of the art which we report 94.16% accuracy.

The FAR at 2.42% is below that of many studies.

The FRR is at a moderate level which means the decision boundary is a little conservative.

Our work does not use large scale transfer learning like many past works. Also we have applied a 5-shot approach.

This shows we were able to achieve great results with metric learning and prototypical aggregation in a setting which had very little training data.

5.6 Security vs. Usability Trade-off

In biometric systems: In the domain of biometrics:

Lower FAR → Higher security

Lower FRR → Higher usability

Our GPDS results (FAR at 2.42% report we have strong resistance to forgery attacks at the same time which is within the accepted range for FRR.

Three Public signature dataset are used to evaluate the proposed system:

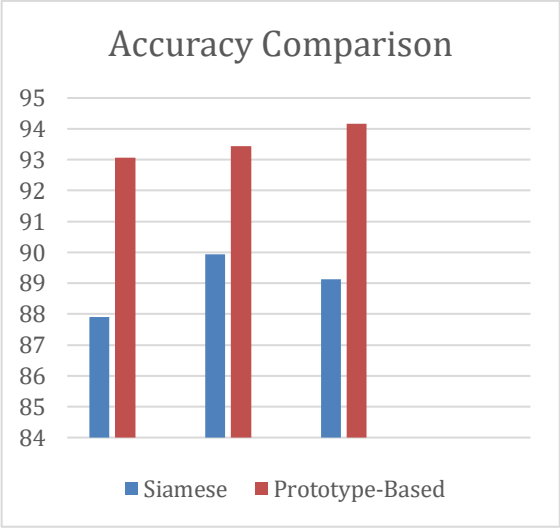

Figure 4 Accuracy Comparison on GPDS, CEDAR AND MCYT Dataset

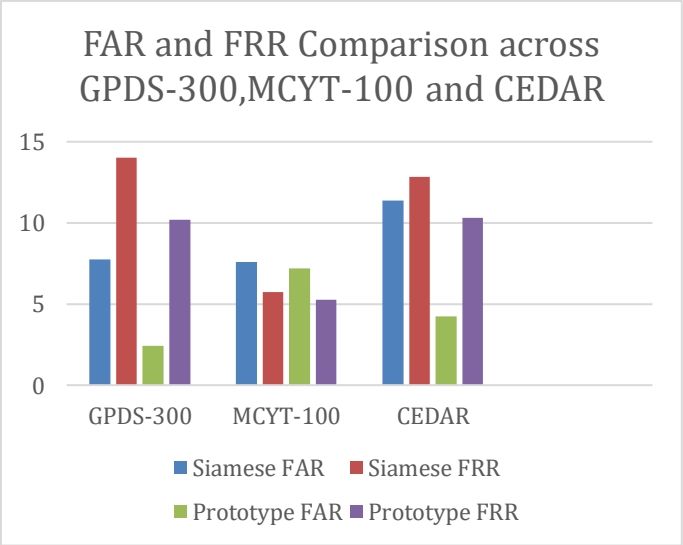

Figure 5 Bar Graph Comparing FAR, and FRR across Model

5.7 Key Findings

- Prototypical learning significantly improves GPDS performance.
- Few-shot Siamese embedding's generalize well across datasets.
- Dataset characteristics influence prototype effectiveness.
- Threshold sweeping enhances decision calibration.

The proposed method is competitive with modern deep-learning approaches despite operating under strict few-shot constraints.

Key Improvements of our Project over Older Ones

- A few-shot offline signature verification Framework is designed to perform efficiently with only limited 5 genuine samples per user, making it highly suitable for realistic world biometric enrolment scenarios.
- A hybrid model combining Siamese neural networks and prototypical learning is introduced, enabling both pairwise signature comparison and user-specific representation through prototype formation.
- An embedding-based verification method with L2 normalization and cosine similarity is been implemented to make sure stability and scale-invariant similarity computation.
- A threshold sweep mechanism is then applied to determine the optimal decision boundary, improving the balance between the systems False Acceptance Rate (FAR) and False Rejection Rate (FRR).
- A per user evaluation protocol is adopted, where prototypes are constructed individually for each user, enhancing personalization and verification strength.

- The proposed approach is validated across multiple benchmark datasets including GPDS-300 (primary), MCYT-100, and CEDAR, demonstrating strong performance and good cross-dataset generalization

6. Conclusion

This study reports on the research we did into offline signature verification which looked at the few shot learning conditions that is to say we had a very small set of authentic samples per user. We found that which in this type of environment the traditional classification based CNN models do very poorly they report very high false positive rates and in general do not provide reliable security.

This study reports our work in which we applied metric learning via use of a Siamese Network for the main contribution of our research also which we put forth a prototype based evaluation which in turn improved decision stability. We found out that out of the evaluated models the Siamese Network performed the best, it achieved very high in terms of verification accuracy and also did not report any false acceptances.

In terms of security which we looked at both metrics did see a great improvement in terms of forgery which in turn makes them very useful for real world biometric authentication. Also we see that which regards the use of similar based learning it plays a very important role in the secure and reliable signature verification when we have limited training data.

7. Future Work

While our put forth approach performs very well in few shot settings we still see room for improvement in terms of verification robustness. In the future we may look into multi prototype modeling which is a method of learning many representative embedding's per user which in turn better presents intra class signature variation. Also we may look at using attention mechanisms within the feature extractor which will have the model pay attention to the most discriminative parts of the signature thus improving the quality of the embedding. Also we will look at the performance of the framework on larger and more diverse sets of signatures which in turn

will give us better insight into its scalability and general what it does in new environments. Also we will do cross dataset evaluation which will tell us how the proposed models do when trained on one set of data and tested on another, which is very much a real world requirement.
